<tr>
<td>2. Li ZC, Dai LY, Jiang LS, Qiu S. Difference in subchondral cancellous bone between postmenopausal women with hip osteoarthritis and osteoporotic fracture: implication for fatigue microdamage, bone microarchitecture, and biomechanical properties. <em>Arthritis Rheum.</em> 2012;64(12):3955-3962.</td>
<td>Observational-Dx</td>
<td>60 patients</td>
<td>To determine whether this difference might be attributable to the different quantity and quality of subchondral cancellous bone in the 2 conditions.</td>
<td>Both the ultimate stress and the elastic modulus of cancellous bone from OA patients were significantly higher than those of cancellous bone from OP patients ($P&lt;0.05$). Compared to cancellous bone from OP patients, the bone volume fraction and trabecular thickness were significantly increased, but bone matrix mineralization was significantly decreased, in cancellous bone from OA patients ($P&lt;0.05$ for each comparison). The microcrack density was significantly higher in OP cancellous bone than in OA cancellous bone ($P&lt;0.001$), irrespective of fatigue loading. In addition, fatigue loading resulted in a significant increase in microcrack density in both OA and OP cancellous bone ($P&lt;0.001$). There was no significant difference in nanoindentation elastic modulus and hardness between cancellous bone from OA and OP patients, as well as between bones with and without fatigue loading.</td>

<td>3. Fredericson M, Jennings F, Beaulieu C, Matheson GO. Stress fractures in athletes. <em>Top Magn Reson Imaging.</em> 2006;17(5):309-325.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review stress fractures in athletes by focusing on MRI, which provides highly sensitive and specific evaluation for bone marrow edema, periosteal reaction as well as detection of subtle fracture lines.</td>
<td>A stress fracture is a partial or complete bone fracture that results from repeated application of stress lower than the stress required to fracture the bone in a single loading. Otherwise healthy athletes, especially runners, sustain stress injuries or fractures. Prevention or early intervention is the preferable treatment. However, it is difficult to predict injury because runners vary with regard to biomechanical predisposition, training methods, and other factors such as diet, muscle strength, and flexibility. Stress fractures account for 0.7% to 20% of all sports medicine clinic injuries. Track-and-field athletes have the highest incidence of stress fractures compared with other athletes. Stress fractures of the tibia, metatarsals, and fibula are the most frequently reported sites. The sites of stress fractures vary from sport to sport (eg, among track athletes, stress fractures of the navicular, tibia, and metatarsal are common; in distance runners, it is the tibia and fibula; in dancers, the metatarsals). In the military, the calcaneus and metatarsals were the most commonly cited injuries, especially in new recruits, owing to the sudden increase in running and marching without adequate preparation. However, newer studies from the military show the incidence and distribution of stress fractures to be similar to those found in sports clinics. Fractures of the upper extremities are relatively rare, although most studies have focused only on lower-extremity injuries. The ulna is the upper-extremity bone injured most frequently. Imaging plays a key role in the diagnosis and management of stress injuries. Plain radiography is useful when positive, but generally has low sensitivity. Radionuclide bone scanning is highly sensitive, but lacks specificity and the ability to directly visualize fracture lines.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review the pathophysiology, risk factors, diagnosis, treatment, and prevention of stress fractures in runners.</td>
<td>Stress fractures are a relatively common entity in athletes, in particular, runners. Physicians and health care providers should maintain a high index of suspicion for stress fractures in runners presenting with insidious onset of focal bone tenderness associated with recent changes in training intensity or regimen. It is particularly important to recognize “high-risk” fractures, as these are associated with an increased risk of complication. A patient with confirmed radiographic evidence of a high-risk stress fracture should be evaluated by an orthopedic surgeon. Runners may benefit from orthotics, cushioned sneakers, interval training, and vitamin/calcium supplementation as a means of stress fracture prevention.</td>

<tr>
<td>5.</td>
<td>Review/Other-Dx</td>
<td>178 patients</td>
<td>To evaluate the incidence and the MRI and scintigraphic appearance of acetabular stress (fatigue) fractures in military endurance athletes and recruits.</td>
<td>Stress fractures are common in endurance athletes and in military populations; however, stress fracture of the acetabulum is uncommon. 12/178 patients (6.7%) in our study had imaging findings consistent with acetabular stress fractures. 7 patterns were identified. 7 of the 12 (58%) patients had acetabular roof stress fractures. In this group, 2 cases of bilateral acetabular roof stress fractures were identified, with a synchronous tensile sided femoral neck stress fracture. The remaining 5/12 (42%) patients had anterior column stress fractures, rarely occurring in isolation, and almost always occurring with inferior pubic ramus stress fracture (4 of 5, or 80%). 1 case of bilateral anterior column stress fractures was identified without additional sites of injury.</td>

<td>8. Lassus J, Tulikoura I, Konttinen YT, Salo J, Santavirta S. Bone stress injuries of the lower extremity: a review. <em>Acta Orthop Scand.</em> 2002;73(3):359-368.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review bone stress injuries of the lower extremity.</td>
<td>Bone stress injuries can cause long-lasting damage, especially in young athletes and military conscripts, if not diagnosed and treated properly. Diagnosis has been traditionally based on clinical, radiographic and scintigraphic examinations, but MRI has become increasingly important. High resolution MRI is particularly valuable for the grading of bone stress injuries. The clinician should be aware of the wide range of bone stress injuries and available diagnostic methods. Early diagnosis is the prerequisite for avoiding long-lasting complications. Most bone stress injuries heal with closed treatment, but surgery is necessary in some cases. They heal well if the diagnosis is not delayed and the treatment adequate.</td>

<td>Observational-Dx</td>
<td>84 patients</td>
<td>To evaluate the use of bone scintigraphy for the diagnosis of stress fractures in athletes and its validity for the prediction of healing time, with a focus on foot injuries.</td>
<td>For the diagnosis of stress injuries (n = 50/93), mean sensitivity, specificity, PPV, NPV, and accuracy were 97.3%, 67.4%, 77.7%, 95.6%, and 83.5%, respectively. Interobserver analysis showed a high agreement between all 3 readers (mean kappa = 0.83). In univariate analysis healing time of grade 3 to 4 stress injuries was significantly higher (median, 87 days; interquartile range, 69–132 days) compared with grade 1 to 2 lesions (median, 63 days; interquartile range, 43–95 days; <em>P</em>=0.0067). Moreover, healing time of scintigraphic high grade stress injuries was significantly longer in a general linear model with adjustment for cofactors (grade, 3-4 vs. 1-2; <em>P</em>=0.033).</td>

<td>12. Liong SY, Whitehouse RW. Lower extremity and pelvic stress fractures in athletes. <em>Br J Radiol.</em> 2012;85(1016):1148-1156.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review the incidence, presentation, radiological findings and management options for athletes with stress fractures of the lower limb.</td>
<td>Stress fractures are relatively common in athletes, particularly in long-distance runners. Strong clinical suspicion in concert with radiological imaging (in the form of plain radiographs, MRI, CT or bone scan) play important roles in the detection of stress injuries in athletes. Early recognition and treatment of stress fractures reduce athletic morbidity and allow timely return to high-level activity. It is therefore important for radiologists to be aware of mechanisms leading to, and locations of, stress injuries, to facilitate timely diagnosis.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>Review occurrence, imaging and differential diagnosis of insufficiency fractures.</td>
<td>Radiographs are still the most widely used imaging method for identification of insufficiency fractures, but sensitivity is limited, depending on the location of the fractures. MRI is a very sensitive tool to visualize bone marrow abnormalities associated with insufficiency fractures. Thin section, MDCT depicts subtle fracture lines allowing direct visualization of cortical and trabecular bone. Bone scintigraphy still plays a role in detecting fractures, with good sensitivity but limited specificity. The most important differential diagnosis is underlying malignant disease leading to pathologic fractures. Bone densitometry and clinical history may also be helpful in confirming the diagnosis of insufficiency fractures.</td>

<td>Review/Other-Dx</td>
<td>378 bone stress injuries in 142 ankles and feet imaged</td>
<td>To assess incidence, location, and type of bone stress injuries of the ankle and foot in military conscripts with ankle and/or foot pain using MRI.</td>
<td>Incidence is 126 per 100,000 person-years. This incidence represents the stress injuries not diagnosable with radiographs and requiring MRIs. Of injuries, 57.7% occurred in the tarsal and 35.7% in the metatarsal bones. Multiple bone stress injuries in one foot were found in 63% of the cases. The calcaneus and fifth metatarsal bone were usually affected alone. Injuries to the other bones of the foot were usually associated with at least one other stress injury. The talus and calcaneus were the most commonly affected single bones. High-grade bone stress injury (grade IV-V) with a fracture line on MRIs occurred in 12% (talus, calcaneus), and low-grade injury (grade I-III) presented only as edema in 88% of the cases.</td>
</tr>
<tr>
<td>27. Sormaala MJ, Niva MH, Kiuru MJ, Mattila VM, Pihlajamaki HK. Stress injuries of the calcaneus detected with magnetic resonance imaging in military recruits. <em>J Bone Joint Surg Am.</em> 2006;88(10):2237-2242.</td>
<td>Observational-Dx</td>
<td>30 recruits displayed calcaneal stress injuries</td>
<td>Retrospective study to assess the anatomic distribution, nature, and healing of calcaneal stress injuries in a group of military recruits based on MRI.</td>
<td>MRI yielded an incidence of 2.6 (95% CI, 1.6 to 3.4) per 10,000 person-years. Most stress injuries of the calcaneus occur in the posterior part of the bone, but a considerable proportion can also be found in the middle and anterior parts. To obtain a diagnosis, MRI is warranted if plain radiography does not show abnormalities in a physically active patient with exercise-induced pain in the ankle or heel.</td>
</tr>
<tr>
<td>28. Sormaala MJ, Niva MH, Kiuru MJ, Mattila VM, Pihlajamaki HK. Bone stress injuries of the talus in military recruits. <em>Bone.</em> 2006;39(1):199-204.</td>
<td>Observational-Dx</td>
<td>51 consecutive recruits displayed bone stress injuries; 56 bone stress injuries 3 reviewers</td>
<td>Retrospective study to assess the incidence, anatomic distribution, and nature of fatigue bone stress injuries of the talus in military recruits based on MRI.</td>
<td>On MRI, the majority of the bone stress injuries of the talus were revealed in the head. A grade IV injury was discovered in 18% of the cases; in the remaining 82%, only grade I-III injuries were ascertained. In all locations, the lower grade bone stress injuries dominated. This study established the incidence of fatigue bone stress injury of the talus and indicated that these injuries are rare but not unseen in military recruits.</td>

<td>Review/Other-Dx</td>
<td>4 patients</td>
<td>To review stress fractures of the olecranon in javelin throwers.</td>
<td>Between the years 1977 and 1984, 4 javelin throwers with a stress fracture of the olecranon were seen and treated. In 1 patient, acute painful dislocation of the fracture occurred during a competitive throw. 2 patients had stress fracture of the tip. The fracture treated conservatively healed in 18 months. The patient treated by excision of the tip was able to throw after 2 months. 2 patients had slightly oblique, more distally located stress fractures, which were treated with a tension band and 2 Kirschner wires. The fractures healed in 4 months. One of the patients had a refracture 11 months after the primary operation. It was successfully treated with a compression screw and 2 bone pegs. Because of the high risk of delayed union and nonunion, stress fractures of the olecranon should be treated operatively in javelin throwers.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review tarsal navicular stress fracture in athletes.</td>
<td>Stress fracture of the tarsal navicular bone is now frequently recognized. The majority of navicular stress fractures are partial fractures in the sagittal plane. They occur mainly in track and field athletes. A number of theories regarding the etiology of this fracture have been proposed. Athletes with a history of vague, activity-related midfoot pain, with associated tenderness over the dorsal proximal navicular ('N' spot) should be suspected of having a navicular stress fracture. Plain radiography frequently fails to demonstrate the fracture, thus radionuclide scanning is the investigation of choice to detect navicular stress injury. A CT scan should be performed to confirm the presence of the fracture. Various methods of treatment have been employed. A minimum of 6 weeks of strict non-weightbearing cast immobilization is the treatment of choice. After removal of the cast, a further 6 week program of rehabilitation with a graduated return to activity, joint mobilization and soft tissue massage is required. Surgery for nonunion or delayed union is rarely required if initial treatment is appropriate.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review the literature regarding stress fractures of the pelvis and legs in athletes.</td>
<td>Intrinsic and extrinsic factors may predict the risk of stress fractures in athletes, including bone health, training, nutrition, and biomechanical factors. Based on their location, stress fractures may be categorized as low- or high-risk, depending on the likelihood of the injury developing into a complete fracture. Treatment for these injuries varies substantially and must account for the risk level of the fractured bone, the stage of fracture development, and the needs of the patient. High-risk fractures include the anterior tibia, lateral femoral neck, patella, medial malleolus, and femoral head. Low-risk fractures include the posteromedial tibia, fibula, medial femoral shaft, and pelvis. MRI is the imaging test of choice for diagnosis.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To describe stress fractures in athletes.</td>
<td>Stress fractures are common injuries in the athletic population. High clinical suspicion is required for the diagnosis because of vague historical and physical features. Bone scans are the gold standard of diagnosis, though MRI and CT may be helpful adjuncts. Most stress fractures do very well with the nonsurgical treatment approach. Some fractures of the proximal diaphysis of the fifth metatarsal, femoral neck fractures, and any displaced, completed fracture require surgery. Consideration must also be given for correctable risk factors and preventive measures must be addressed.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To describe the pathoanatomy, cause, clinical assessment, and treatment options will facilitate the care of athletes with a femoral stress fracture and the return to a preinjury level of competition.</td>
<td>Femoral stress fractures represent an uncommon but important lower-extremity injury in athletes and soldiers. Careful assessment of the involved and contralateral lower extremity and the spine is required to make the diagnosis. Based on a review of the literature, specific treatment is based on individual patient assessment. In most cases, nonoperative management results in an excellent outcome. Certain fractures will require operative intervention to prevent displacement or to reduce a displaced fracture and return stability to the lower extremity. Complications in athletes with femoral stress fractures are rare. Most athletes can expect to return to their preinjury level of competition, if they are compliant with the treatment plan.</td>

<td>Review/Other-Dx</td>
<td>423 scientific publications</td>
<td>To review the reported research on the causes of and risk factors for stress fracture, to determine what is known about the prevention of stress fracture and to make recommendations for a systematic approach to future research and prevention.</td>
<td>This review summarizes an extensive body of literature on stress fractures. It also highlights how little we know about what works to prevent one of the most common and potentially serious sports- and exercise-related overuse injuries. The available research suggests that for many persons, stress fractures and other physical training-related injuries can be prevented by reducing the amounts of weight-bearing exercise performed without sacrificing fitness. The data also suggest that the most sedentary and least physically fit persons are most vulnerable to stress fractures when starting a vigorous exercise program and that they would benefit most from starting exercise gradually and reducing training volume. Until more definitive solutions become available, a common-sense approach to training and overuse injury prevention must be recommended.</td>

<td>Review/Other-Dx</td>
<td>14 runners</td>
<td>To evaluate tibial stress injuries in runners, develop a grading system based on MRI findings, and try to identify clinical parameters correlating with more severe grades of injury.</td>
<td>Medial tibial pain in runners has traditionally been diagnosed as either a shin splint syndrome or as a stress fracture. Our work using MRI suggests that a progression of injury can be identified, starting with periosteal edema, then progressive marrow involvement, and ultimately frank cortical stress fracture. 14 runners, with a total of 18 symptomatic legs, were evaluated and, within 10 days, referred for radiographs, a technetium bone scan, and a MRI scan. In 14 of the 18 symptomatic legs, MRI findings correlated with an established technetium bone scan grading system and more precisely defined the anatomic location and extent of injury. We identified clinical symptoms, such as pain with daily ambulation and physical examination findings, including localized tibial tenderness and pain with direct or indirect percussion that correlated with more severe tibial stress injuries. When clinically warranted, we recommend MRI over bone scan for grading of tibial stress lesions in runners. MRI is more accurate in correlating the degree of bone involvement with clinical symptoms, allowing for more accurate recommendations for rehabilitation and return to impact activity. Additional advantages of MRI include lack of exposure to ionizing radiation and significantly less imaging time than three-phase bone scintigraphy.</td>

<td>53. Matheson GO, Clement DB, McKenzie DC, Taunton JE, Lloyd-Smith DR, MacIntyre JG. Stress fractures in athletes. A study of 320 cases. <em>Am J Sports Med.</em> 1987;15(1):46-58.</td>
<td>Review/Other-Dx</td>
<td>320 patients</td>
<td>To provide descriptive data from 320 cases of bone scan-positive stress fractures in athletes and to document the results of conservative treatment.</td>
<td>The most common bone injured was the tibia (49.1%), followed by the tarsals (25.3%), metatarsals (8.8%), femur (7.2%), fibula (6.6%), pelvis (1.6%), sesamoids (0.9%), and spine (0.6%). Stress fractures were bilateral in 16.6% of cases. A significant age difference among the sites was found, with femoral and tarsal stress fractures occurring in the oldest, and fibular and tibial stress fractures in the youngest. Running was the most common sport at the time of injury but there was no significant difference in weekly running mileage and affected sites. A history of trauma was significantly more common in the tarsal bones. The average time to diagnosis was 13.4 weeks (range, 1 to 78) and the average time to recovery was 12.8 weeks (range, 2 to 96). Tarsal stress fractures took the longest time to diagnose and recover. Varus alignment was found frequently, but there was no significant difference among the fracture sites, and varus alignment did not affect time to diagnosis or recovery. Radiographs were taken in 43.4% of cases at the time of presentation but were abnormal in only 9.8%. A group of bone scan-positive stress fractures of the tibia, fibula, and metatarsals (N = 206) was compared to a group of clinically diagnosed stress fractures of the same bone groups (N = 180), and no significant differences were found.</td>

<td>54. Tsiridis E, Upadhyay N, Giannoudis PV. Sacral insufficiency fractures: current concepts of management. <em>Osteoporos Int.</em> 2006;17(12):1716-1725.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To raise awareness and outline the clinical presentation, methods of diagnosis and treatment of sacral insufficiency fractures.</td>
<td>Insufficiency fractures represent a special category of stress fractures that occur in bones with reduced mineral content and elastic resistance. Sacral insufficiency fractures, a well-defined subgroup of the latter group, are not uncommon, but lack of clinical suspicion results in many being undiagnosed. Sacral insufficiency fractures are set to become an important clinical entity of both social and economic significance as the Western population ages. Subtle clinical presentations and signs coupled with radiographic findings that can mimic other unrelated or overlapping conditions, such as sacroiliac joint infection, spinal stenosis and metastatic bone disease, often make sacral insufficiency fracture diagnosis a challenge.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To present select examples of fractures that underscore imaging features that help distinguish stress fractures from pathologic fractures.</td>
<td>Whereas stress fractures occur in normal or metabolically weakened bones, pathologic fractures occur at the site of a bone tumor. Unfortunately, stress fractures may share imaging features with pathologic fractures on plain radiography, and therefore other modalities are commonly utilized to distinguish these entities. Additional cross-sectional imaging with CT or MRI as well as scintigraphy and PET scanning is often performed for further evaluation. For the detailed assessment of a fracture site, CT offers a high-resolution view of the bone cortex and periosteum which aids the diagnosis of a pathologic fracture. The character of underlying bone marrow patterns of destruction can also be ascertained along with evidence of a soft tissue mass. MRI, however, is a more sensitive technique for the detection of underlying bone marrow lesions at a fracture site. In addition, the surrounding soft tissues, including possible involvement of adjacent muscle, can be well evaluated with MRI. While bone scintigraphy and FDG-PET are not specific, they offer a whole-body screen for metastases in the case of a suspected malignant pathologic fracture.</td>

<td>63. Steib-Furno S, Luc M, Pham T, et al. Pregnancy-related hip diseases: incidence and diagnoses. <em>Joint Bone Spine.</em> 2007;74(4):373-378.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To report the incidence of gestational and postpartum hip diseases and evaluate their incidence.</td>
<td>During the 2-year prospective survey, 3 patients (4 hips) of pregnancy-related hip disease were observed over 4900 pregnancies (1 case of transient osteoporosis of the hip and 2 cases of occult fracture of the femoral head). During the 15-year retrospective study, 12 patients (17 hips) with hip diseases during pregnancy or early postpartum were identified. There were 6 patients (9 hips) with transient osteoporosis of the hip, 4 patients (6 hips) with occult fracture of the femoral head, 1 patient with osteonecrosis of the femoral head, and 1 coxitis in a patient with ankylosing spondylitis. Differentiating diagnosis between transient osteoporosis of the hip and occult fractures could only be made by MRI. 5 of the 6 women with transient osteoporosis of the hip had osteopenia at the lumbar spine at dual energy X-ray absorptiometry. The 4 women with occult fractures had either osteopenia or osteoporosis at the lumbar spine.</td>

<td>Observational-Dx</td>
<td>18 women</td>
<td>To assess the incidence, time of appearance and evolution of radiation-induced insufficiency fractures of the female pelvis with MRI.</td>
<td>16 (89%) of 18 patients (7 premenopausal and 9 postmenopausal) showed findings compatible with insufficiency fractures. 13 patients had more than 1 lesion. The first fracture was detected between 3 and 12 months after the end of radiation therapy. During the study, the fractures associated with edema subsided without treatment in 41 (79%) of 52 lesions in 15 (94%) of 16 patients. Fractures were confirmed with additional imaging in all 16 patients (CT in 14 patients and bone scanning in 9 patients).</td>

<td>65.</td>
<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review the benign entities that may be mistaken by the radiologist for a malignancy and thus lead to needless referral to an orthopedic oncologist.</td>
<td>The MRI appearance of osteonecrosis, Paget disease, benign bone lesions, and rheumatologic conditions may be confusing; in such circumstances, radiographic findings may help formulate a correct diagnosis. Knowledge of the common locations and appearances of bursae and ganglia is necessary so that radiologists do not misinterpret these benign entities as soft-tissue sarcomas. Soft-tissue trauma and inflammation also may mimic tumors at MRI, but a familiarity with the imaging patterns of nonneoplastic change in muscle allows the avoidance of misinterpretation. The clinical history, as always, is an important component of proper diagnosis. The radiologist can be especially useful to both the clinician and the patient by recognizing entities that are highly unlikely to represent malignancy and by confidently reporting those entities as benign, thereby sparing the patient an unnecessary trip to the orthopedic oncologist.</td>

<tr>
<td>66.</td>
<td>Observational-Dx</td>
<td>21 patients</td>
<td>To assess whether in-phase/opposed-phase imaging of the spine can differentiate these 2 entities.</td>
<td>21 patients had 49 vertebral lesions, consisting of 20 malignant and 29 benign fractures. There was a significant difference ($P&lt;.001$, Student t test) in the mean signal intensity ratio for the benign lesions (mean, 0.58; SD, 0.02) compared with the malignant lesions (mean, 0.98; SD, 0.095). If a signal intensity ratio of 0.80 as a cutoff is chosen, with $&gt;0.8$ defined as malignant and $&lt;0.8$ defined as a benign result, in-phase/opposed-phase imaging correctly identified 19/20 malignant lesions and 26/29 benign lesions (sensitivity, 0.95; specificity, 0.89).</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To review the clinical strength of planar bone imaging, in comparison SPECT, SPECT/CT, FDG-PET imaging and briefly reviews the re-emergence of 18F sodium fluoride bone PET imaging.</td>
<td>The power of bone imaging lies in the physiological uptake and pathophysiologic behavior of Tc-99m diphosphonates. Its clinical utility, sensitivity and specificity was established based on planar imaging data. Planar bone imaging data are often sufficient for diagnosis and may be enhanced by SPECT. New imaging modalities, including FDG-PET, CT and MR are complementary to Tc-99m bone imaging. FDG-PET and Tc-99m bone imaging reflect different biological processes (FDG uptake by tumor cells; methylene diphosphonate uptake by osteoblastic activity). We can lower radiation doses by prescribing lower injected doses and minimizing unnecessary additional imaging. We are physicians and should all adopt a “value-added” approach to image interpretation.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>To determine the current trend in the number and incidence of OP pelvic fractures in Finland, a country with a Caucasian population of 5 million.</td>
<td>The total number of OP pelvic fractures increased considerably in Finland during the study period, from 128 in 1970 to 913 in 1997, an average increase of 23% a year. The corresponding fracture incidence (per 100,000 persons 60 years of age or older) was 20 in 1970 and 92 in 1997. The mean age of the patients also increased, from 74 years (1970) to 80 years (1997). Despite this, the age-adjusted incidence of OP pelvic fractures also showed a steady increase from 1970 to 1997: in women, from 31 to 103, and in men, from 13 to 38 (relative increases were 232% and 192%, respectively). If this trend continues, the current number of OP pelvic fractures in this country (about 900 fractures per year) may treble by the year 2030 (about 2,700 fractures per year).</td>

<td>70.</td>
<td>Review/Other-Dx</td>
<td>1 case</td>
<td>A case of postpartum sacral stress fracture.</td>
<td>To date, only 8 postpartum sacral stress fractures have been reported in the literature. A 32-year-old woman presented with low-back and right buttock pain that started 15 days after uneventful cesarean section delivery. Imaging studies revealed a right sacral stress fracture. Lumbar spine and femoral neck bone mineral density were normal and, except for pregnancy and lactation, no risk factors for osteoporosis were identified. There was no history of trauma, excessive weight gain, strenuous physical activity, or contribution of mechanical factors. The question remains whether this is an insufficiency fracture or a fatigue fracture. Clinicians should consider sacral fracture during pregnancy and the postpartum period as a diagnostic possibility in patients with low-back and/or buttock pain.</td>
<td>4</td>
</tr>
<tr>
<td>71.</td>
<td>Review/Other-Dx</td>
<td>1 case</td>
<td>To present a case of a young, postpartum, recreational runner who developed low back pain and radicular symptoms suggestive of L5 radiculopathy found to be secondary to sacral stress fracture.</td>
<td>Sacral stress fractures are a rare entity that may occur in exercising postpartum women. The specific explanation for these fractures remains unclear. Symptoms include low back pain and radicular pain, which may initially be attributed to a diskogenic cause. Overall, these patients have a good clinical outcome. Rehabilitation, including light weight-bearing exercise, is essential for bone healing and may be performed with the use of adequate pain control. Underlying causes for fracture, such as osteoporosis or other metabolic bone disease, should ideally be ruled out to correct potentially treatable conditions. Clinicians caring for postpartum exercising women should have a high clinical suspicion for sacral stress fracture in patients with low-back, buttock, or groin pain.</td>

<td>Review/Other-Dx</td>
<td>10 cases</td>
<td>To describe 10 cases of spontaneous sacral insufficiency fractures, confirmed by CT, characterized by the onset of acute low-back pain.</td>
<td>Sacral insufficiency fractures are an often unsuspected cause of low-back pain in elderly women with osteopenia who have sustained unknown or only minimal trauma. Differential clinical and radiographic diagnosis of these fractures is often difficult. Recognition of the characteristic scintigraphic patterns in sacral fractures, which are frequent in osteopenic patients, could avoid mistaken diagnoses and unnecessary tests or treatment. One of the striking features of these sacral fractures is their invariable location. The fractures extend vertically in the sacral alae, parallel to the sacroiliac joints. They are located just lateral to the margins of the lumbar spine. This distribution suggests that such fractures could be partially caused by weight-bearing transmitted through the spine.</td>

<td>Review/Other-Dx</td>
<td>N/A</td>
<td>A literature review of appropriate databases, articles and relevant institutional protocols was performed. Data was sought regarding any adverse effects of diagnostic radiation in pregnancy, fetal absorbed dose of diagnostic radiation and how the timing of exposure and form of administration might influence these effects.</td>
<td>The estimated radiation dose for a fetus from background sources as well as medical imaging was identified. Most diagnostic radiation procedures will lead to a fetal absorbed dose of &lt;1 mGy for imaging beyond the abdomen/pelvis and &lt;10 mGy for direct or nuclear medicine imaging. Potential adverse outcomes related to radiation exposure during pregnancy include teratogenicity, genetic damage, intrauterine death and increased risk of malignancy. The only adverse effect statistically proven at the dose levels associated with diagnostic radiation procedures is a very small increase in childhood malignancy, with an estimated increase of one additional cancer death per 1700 10 mGy exposures. The important exception was the risk to the fetal thyroid from radioiodine exposure after 12 weeks' gestation.</td>
