RIB FRACTURES

Expert Panel on Thoracic Imaging: Travis S. Henry, MD; Edwin F. Donnelly, MD, PhD; Phillip M. Boiselle, MD; Traves D. Crabtree, MD; Mark D. Iannettoni, MD; Geoffrey B. Johnson, MD, PhD; Ella A. Kazerooni, MD; Archana T. Laroia, MD; Fabien Maldonado, MD; Kathryn M. Olsen, MD; Carlos S. Restrepo, MD; Kyungran Shim, MD; Arlene Sirajuddin, MD; Carol C. Wu, MD; Jeffrey P. Kanne, MD.

Summary of Literature Review

Introduction/Background

Rib fracture is the most common thoracic injury and is present in 10% of all traumatic injuries and in almost 40% of patients who sustain severe nonpenetrating trauma [1,2]. Rib fractures typically affect the fifth through ninth ribs. This may be due to the fact that the shoulder girdle affords relative protection to the upper ribs, and the lower ribs are relatively mobile and may deflect before fracturing [1].

Although rib fractures can produce significant morbidity, the diagnosis of associated complications (such as pneumothorax, hemothorax, pulmonary contusion, atelectasis, flail chest, cardiovascular injury, and injuries to solid and hollow abdominal organs) is arguably more important as these complications are likely to have the most significant clinical impact [1,2]. When isolated, rib fractures have a relatively low morbidity and mortality [2,3].

Treatment of rib fractures is generally aimed at pain control and avoidance of respiratory distress and intubation, but the presence of multiple rib fractures, underlying organ injury, or in an elderly patient especially, may warrant transfer from a community hospital to tertiary care center [2,4-6].

Discussion of Procedures by Variant

Variant 1: Suspected rib fractures from minor blunt trauma (injury confined to ribs). Initial imaging.

This variant refers to rib fractures resulting from minor blunt trauma. For severe cases of trauma, please refer to the ACR Appropriateness Criteria® topic on “Blunt Chest Trauma” [7] and the ACR Appropriateness Criteria® topic on “Major Blunt Trauma,” which will be made available on the ACR website when completed. For suspected stress fractures, please refer to the ACR Appropriateness Criteria® topic on “Stress (Fatigue/Insufficiency) Fracture, Including Sacrum, Excluding Other Vertebrae” [8].

Radiography Chest

In combination with the physical examination, a standard posteroanterior (PA) chest radiograph should be the initial diagnostic test for detection of rib fractures. Despite the low sensitivity of the chest radiograph, which may miss 50% of rib fractures [2], studies suggest that failure to detect fractures does not necessarily alter patient management or outcome in uncomplicated cases. A review of 271 patients who presented to a community hospital emergency department after minor trauma showed no difference in treatment (use of pain medications, etc) between patients who did and did not have rib fractures diagnosed on physical examination or radiographs [3]. In a study of 552 patients who had blunt chest trauma and resultant rib fracture (diagnosed on clinical or radiographic grounds), 93% of affected patients ultimately resumed daily activities without significant disability [2]. The chest radiograph may detect complications that are more important than the rib fractures themselves, such as pneumothorax, hemothorax, flail chest, or contusion [1,2]. Although a flail chest can usually be diagnosed at physical examination, it is conceivable that in a heavy patient a flail chest could be missed by clinical examination, but a chest radiograph almost always shows the displaced fragments.

Dual-energy chest radiography with bone subtraction imaging has failed to show improved detection when

ACR Appropriateness Criteria®

Rib Fractures
compared with standard radiographs. A review of 39 patients with a total of 204 rib fractures showed no statistically significant difference in sensitivity, specificity, or level of confidence between standard images and dual-energy subtraction images [9].

**Radiography Rib Views**

While still performed in many practices, rib detail radiograph series rarely add additional information to the PA film that would change treatment as has been shown in two retrospective studies. In a review of 422 patients presenting to a university-affiliated emergency department for suspected rib fracture, Shuaib et al [10] found that rib series resulted in a change of management in only one patient (0.23%). Moreover, these authors found that, compared to standard PA radiographs, rib series negatively impacted patient care by prolonging report turnaround time [10].

Hoffstetter et al [11] retrospectively reviewed 609 patients that underwent rib series in the emergency department and found that while diagnosing a higher number of rib fractures as compared to PA radiographs alone, there was no statistically significant difference in the number of patients who received medical treatment. If rib series are to be performed, Park et al [12] showed that interpreting images with both conventional grayscale and inverted grayscale views may improve detection of rib fractures, although this study did not assess if the improved detection had an effect on outcomes.

**CT Chest**

The increased sensitivity of CT for the detection of rib fractures does not necessarily alter the management or clinical outcomes of patients without associated injuries. Kea et al [13] reported that CT detected rib fractures in 66 of 589 patients (11%) who had initial chest radiographs interpreted as normal at a level I trauma center, but none of the rib fractures were considered of major clinical significance.

The presence and number of rib fractures, and the degree of displacement of the fractures, may carry prognostic significance. Thus, detection of rib fractures by CT may be indicated under certain circumstances (especially if severe injury is suspected). Bugaev et al [14] retrospectively reviewed 245 patients that presented to a level 1 trauma center for a number of rib fractures and degree of displacement. They found that the number of rib fractures and the degree of fracture fragment displacement accurately predicted subsequent opioid requirements.

In contrast, an outcomes analysis by Livingston et al [15] reviewed 388 patients with rib fractures who underwent both chest radiography (anteroposterior, supine) and chest CT and correlated the presence of rib fractures with pulmonary morbidity and mortality. They reported that although rib fractures were detected on only 46% of patients’ initial chest radiographs, the presence of rib fractures or underlying parenchymal abnormality on radiography was associated with increased pulmonary morbidity (odds ratio, 3.8) compared with fractures only detected by CT.

Rib fractures are associated with pulmonary complications, including atelectasis, impaired clearance of secretions, pneumonia, and adult respiratory distress syndrome [2,5,6]. Increased number of rib fractures has been shown to directly correlate with increasing morbidity and mortality, and this effect is greater in patients 65 years of age or older, many of whom have additional comorbid conditions that contribute to poor cardiopulmonary reserve [2,4-6]. Chapman et al [16] recently proposed a “RibScore” using 6 different CT variables: (1) ≥6 rib fractures, (2) bilateral fractures, (3) flail chest, (4) ≥3 severely displaced fractures, (5) first rib fracture, or (6) at least 1 fracture in all 3 anatomic areas (anterior, lateral, and posterior), where higher scores predicted adverse pulmonary outcomes.

Patients with rib fractures from a high-energy mechanism or with a high clinical suspicion of intrathoracic or intra-abdominal injury may warrant further evaluation with contrast-enhanced CT, whereas a low-energy injury or normal physical examination may obviate further testing. Dubinsky and Low [17] studied 69 patients with nonthreatening trauma (stable vital signs with no evidence of cardiac injury, solid or hollow viscus rupture, or fractures associated with significant blood loss) and found that neither rib studies nor chest radiographs were of clinical benefit in this scenario, but they concluded that clinical evidence of a complicated injury, such as pneumothorax, hemothorax, or flail chest, may warrant further evaluation.

Similarly, Schurink et al [18] studied patients with lower rib fractures (ribs 7 through 12) and found that the negative predictive value of a negative physical examination for abdominal injury that is due to low-energy impact was 100%, but in patients with multiple injuries, lower rib fractures were associated with abdominal organ injury in 67% of patients. Matthes et al [19] found no association between right-sided lower rib fractures in 55
trauma patients with hepatic injury when matched with 55 trauma patients without hepatic injury (there was a slight negative association of hepatic laceration with left-sided fractures) but ultimately concluded that the absence of rib fractures could not rule out hepatic injury. Thus, in patients with multiple injuries and lower rib fractures, contrast-enhanced CT might be indicated even in the setting of a normal clinical examination.

Several studies have demonstrated a high prevalence of radiographically detected rib fractures in patients with aortic injury, although the positive predictive value is low. In a large prospective multicenter trial involving 50 trauma centers in North America, Fabian et al [20] reported multiple rib fractures in 46% of 274 patients with blunt aortic injury. Mirvis et al [21] found fractures of ribs 1 through 4 in 18% of 41 patients with traumatic aortic injury proved by angiography but with a positive predictive value of only about 21%. Lee et al [22] studied 548 patients who underwent angiography to evaluate for aortic injury and concluded that rib fractures were the only type of thoracic skeletal injury that had a higher incidence in patients with aortic injury (58%) versus those without aortic injury (43%), but the positive predictive value was only 14.8%. This has also been shown at autopsy, where Williams et al [23] retrospectively reviewed 530 motor vehicle fatalities. In 90 victims, 105 aortic injuries were found, and 78% had multiple rib fractures, including 42% with fractures of the first rib.

In contrast, there is some evidence that rib fractures detected with CT (given the increased sensitivity) may not be associated with an increased risk of aortic injury. A review of 185 patients with rib fractures detected on spine CT found no association between presence of first-rib or second-rib fracture and the incidence of aortic injury on subsequent CT [24]; however, ribs 3 through 12 were not assessed. Increased likelihood of injury to the adjacent subclavian and innominate vessels has been reported with displaced first-rib and second-rib fractures, but this injury can usually be suspected on clinical grounds or from a chest radiograph [25].

**US Chest**

Several articles have noted that ultrasound (US) can detect fractures not seen on conventional radiographs [26-28]. Griffith et al [28] compared US and radiography (chest radiography plus one oblique rib radiograph) in 50 patients and found that radiographs detected only 8 of 83 (10%) sonographically detected rib fractures and were positive in only 6 of the 39 patients who had demonstrated fractures. In this study, US allowed evaluation of the costochondral junction, the costal cartilage, and the ribs and was able to show nondisplaced fractures.

Kara et al [26] found rib fractures in 40.5% of 37 patients with minor blunt chest trauma and negative radiographs by using US; osseous fractures were more common in the elderly, and duration of pain was significantly longer in these patients compared to those with chondral injuries [26-28]. However, Hurley et al [29] found US to be only marginally superior to conventional radiographs, and its routine use was not indicated because of the lengthy time of the examination, averaging 13 minutes in this series, and patient discomfort from the pressure of the US probe, particularly since identification of the fracture was unlikely to impact patient care.

**Bone Scan Whole Body**

Nuclear medicine bone scans are sensitive but not specific for detection of rib fracture [30]. Bone scans are most commonly used for detection of osseous involvement in systemic processes (eg, metastatic disease) and may result in false-positive diagnosis of malignancy in a patient with rib fractures, although the pattern of tracer uptake can often help differentiate the two processes [30]. Bone scans have limited use in distinguishing acute and subacute or chronic rib fractures as they will usually be positive within 24 hours after an injury, but the return to normal can be slow (79% by 1 year, 93% by 2 years, and 100% in 3 years) [31]. Furthermore, patients with known malignancy and benign rib fractures may exhibit false-positive findings on PET using the tracer fluorine-18-2-fluoro-2-deoxy-D-glucose (FDG) studies performed 17 days to 8 weeks after injury [32].

**Variant 2: Suspected rib fractures after cardiopulmonary resuscitation (CPR). Initial imaging.**

**Radiography Chest**

Multiple studies [33-35] have shown that rib fractures are under-reported on radiography performed following cardiopulmonary resuscitation (CPR). In a retrospective analysis of 40 patients who survived CPR, Kim et al [33] reported that CT detected rib fractures in 26 patients (65%); whereas, anteroposterior chest radiography detected fractures in only 10 of the patients. Lederer et al [34] found that radiography detected only 14% of rib fractures compared to autopsy in 19 patients.

Rib fractures from CPR are more commonly anterior, on the left side, and are more numerous in the elderly [34]. The diagnosis of such fractures in CPR survivors may be important since approximately half of CPR survivors with rib fractures experience complications, and the presence of rib fractures in these patients may impair
ventilation and compromise recovery. It should be noted that many of these patients are examined with portable supine radiography, which may contribute to underdiagnosis.

**Radiography Rib Views**
There is no strong indication in the literature that radiography rib series serves any significant use as an initial imaging modality to detect rib fractures after CPR.

**US Chest**
While focused US of the chest wall is more sensitive for detection of rib fractures than radiography in trauma patients [28], there is no direct evidence assessing the use of US in patients after CPR.

**Bone Scan Whole Body**
There is no strong indication in the literature that bone scan serves any significant use as an initial imaging modality to detect rib fractures after CPR.

**CT Chest**
As described above, chest CT is more sensitive than radiography for the detection of rib fractures after CPR. Moreover, CT may show fracture-related complications that are radiographically occult. Kim et al [33] reported that CT found fracture-related complications in 6 of 40 patients (15%) who received CPR, including 1 pneumothorax, 1 subclavian vein injury, and 4 chest wall hematomas. This study did not indicate whether intravenous (IV) contrast was used, nor did it indicate whether CT was performed specifically for evaluation of rib fractures, or if the rib fractures were an incidental finding on a CT performed for other means (eg, suspected pulmonary embolism).

Despite this evidence that CT is sensitive for detection of CPR-associated rib fractures, no data exists in the literature that shows that the increased rate of rib fracture diagnosis affects a patient’s long-term management or prognosis.

**Variant 3: Suspected pathologic rib fracture. Initial imaging.**

**Radiography Chest**
Pathologic fractures may result from metabolic disorders or neoplasm, including primary bone tumor, metastatic disease of intrathoracic or extrathoracic primary, hematologic malignancy (eg, multiple myeloma, lymphoma), or direct extension of a tumor in the thorax. A PA chest radiograph may be sufficient for diagnosis of a pathologic fracture (or provide clues to an underlying diagnosis), but further evaluation using such modalities as CT, bone scan, or FDG-PET may be necessary to further characterize a lesion detected on radiography or to search for radiographically occult lesions [36-38].

**Radiography Rib Views**
There is no strong indication in the literature that radiography rib series serves any significant use as an initial imaging modality to detect suspected pathologic rib fractures.

**US Chest**
There is no strong indication in the literature that US serves any significant use as an initial imaging modality to detect rib fractures.

**CT Chest**
CT may be useful for characterizing a pathologic fracture, and some features may be helpful in differentiating a primary malignant tumor of bone from metastasis [36]. CT may also be helpful to search for a primary malignancy in patients with a suspected pathologic fracture; however, there is no strong indication that CT serves a significant use as the initial imaging modality to detect pathologic rib fractures.

**Bone Scan Whole Body**
Bone scans have a high sensitivity (>95%) but a low specificity for detection of pathologic rib fractures [30]. The distribution of abnormalities may serve as a useful clue in differentiating metastasis from post-traumatic fractures.

**FDG-PET/CT Skull Base to Mid-Thigh**
FDG-PET/CT may be useful to further characterize a lesion detected on radiography or to search for radiographically occult lesions [36,37]. There is no strong indication in the literature that FDG-PET/CT should be the initial imaging modality to detect suspected pathologic rib fractures.
Summary of Recommendations

- **Variant 1**: A radiograph of the chest is usually appropriate for the initial imaging of suspected rib fractures from minor blunt trauma (injury confined to ribs).
- **Variant 2**: A radiograph of the chest is usually appropriate for the initial imaging of suspected rib fractures after cardiopulmonary resuscitation.
- **Variant 3**: A radiograph of the chest is usually appropriate for suspected pathologic rib fracture with CT chest without IV contrast or Bone scan whole body as complimentary to the chest radiography.

Supporting Documents

The evidence table, literature search, and appendix for this topic are available at [https://acsearch.acr.org/list](https://acsearch.acr.org/list). The appendix includes the strength of evidence assessment and the final rating round tabulations for each recommendation.

**Relative Radiation Level Information**

Potential adverse health effects associated with radiation exposure are an important factor to consider when selecting the appropriate imaging procedure. Because there is a wide range of radiation exposures associated with different diagnostic procedures, a relative radiation level (RRL) indication has been included for each imaging examination. The RRLs are based on effective dose, which is a radiation dose quantity that is used to estimate population total radiation risk associated with an imaging procedure. Patients in the pediatric age group are at inherently higher risk from exposure, because of both organ sensitivity and longer life expectancy (relevant to the long latency that appears to accompany radiation exposure). For these reasons, the RRL dose estimate ranges for pediatric examinations are lower as compared with those specified for adults (see Table below). Additional information regarding radiation dose assessment for imaging examinations can be found in the ACR Appropriateness Criteria® [Radiation Dose Assessment Introduction](#) document [39].

*RRL assignments for some of the examinations cannot be made, because the actual patient doses in these procedures vary as a function of a number of factors (eg, region of the body exposed to ionizing radiation, the imaging guidance that is used). The RRLs for these examinations are designated as “Varies.”

## References

The ACR Committee on Appropriateness Criteria and its expert panels have developed criteria for determining appropriate imaging examinations for diagnosis and treatment of specified medical condition(s). These criteria are intended to guide radiologists, radiation oncologists and referring physicians in making decisions regarding radiologic imaging and treatment. Generally, the complexity and severity of a patient’s clinical condition should dictate the selection of appropriate imaging procedures or treatments. Only those examinations generally used for evaluation of the patient’s condition are ranked. Other imaging studies necessary to evaluate other co-existent diseases or other medical consequences of this condition are not considered in this document. The availability of equipment or personnel may influence the selection of appropriate imaging procedures or treatments. Imaging techniques classified as investigational by the FDA have not been considered in developing these criteria; however, study of new equipment and applications should be encouraged. The ultimate decision regarding the appropriateness of any specific radiologic examination or treatment must be made by the referring physician and radiologist in light of all the circumstances presented in an individual examination.
