Clinical Condition: Radiologic Management of Lower Gastrointestinal Tract Bleeding

Variant 1: Lower GI tract bleeding. Active bleeding with hematochezia or melena in a hemodynamically stable patient. Next procedure/intervention.

Acute gastrointestinal (GI) tract bleeding remains a major cause of morbidity and mortality despite advances in management. The mortality rate is around 10% but increases to 40% in cases of massive bleeding associated with hemodynamic instability or the requirement for transfusion of more than 4 units of blood.

Acute lower gastrointestinal (LGI) tract bleeding is defined as bleeding into the small bowel distal to the ligament of Treitz, or bleeding into the large bowel. It may present as either melena or hematochezia, depending on the site. Causes of LGI bleeding include inflammatory bowel disease, neoplasms, stress ulcers, surgical anastamoses, vascular lesions such as angiodysplasia, and diverticulitis.

Diagnostic and therapeutic options for LGI bleeding are discussed in detail under the discussions by variants. Diagnostic options include colonoscopy, Tc-99m red blood cell (RBC) scan, contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), and transcatheter arteriography. Therapeutic options can be facilitated by transcatheter arteriography, colonoscopy, and surgery.

Discussion by Variant

Variant 1: Lower GI tract bleeding. Active bleeding with hematochezia or melena in a hemodynamically stable patient. Next procedure/intervention.

Radiological tests commonly used include radionuclide scans, CT, and transcatheter arteriography. Radionuclide scans have traditionally been the initial diagnostic test since they are more sensitive than arteriography for detecting slower rates of bleeding (approximately 0.05 to 0.1 mL/min, compared to 0.5 to 1.0 mL/min for angiography). However, radionuclide scans frequently provide inaccurate localization of the site of bleeding. Several recent studies reported incorrect localization in 10%–25% of cases, some of which led to wrong site surgery [1,2]. Despite the sensitivity of radionuclide scans one of these studies [2] also showed a 55% rate of false-negative studies when the diagnosis was confirmed by other means.

CT scanning has been shown to have the ability to detect bleeding as low as 0.3 mL/min [3] and in many centers is replacing nuclear medicine scans for localization of bleeding. Although theoretically CT is less sensitive to bleeding than nuclear medicine scans, studies have shown the sensitivity of CT to range from 79% to 100% [4-8]. These studies also demonstrated that with CT the specificity and diagnostic accuracy are also quite good (50%–100% and 74%–98%, respectively). A meta-analysis that included 22 studies and 672 patients showed that sensitivity and specificity for CT were 85% and 92%, respectively [9]. Importantly, a negative CT angiography (CTA) is a good indicator that nothing else may need to be done. A review of 62 patients with negative CTA showed that 77.4% did not rebleed nor require further interventions [10]. In another study, no intervention was needed in any patient who was hemodynamically stable at the time of their negative CTA [11].

In addition to being more readily available and quicker to perform than radionuclide scans, CT has a number of other advantages as an initial test to localize LGI bleeding. It can often yield a diagnosis of the pathologic cause of the bleeding sometimes even if the patient is no longer actively bleeding. In one study [12], CT identified the pathology preoperatively in 50% of cases. Defining the cause of bleeding can help determine prognosis as well as
the best options for treatment. This allows patients who have lesions that are unfavorable for embolization to be triaged directly to surgery. In one series, as many as 40% of the cases could be triaged directly to surgery as a result of the CTA [11]. CT can also provide information about the arterial anatomy. It can identify variant anatomy or vessel occlusions that would influence subsequent transcatheter arteriography/intervention (TAI).

Urgent colonoscopy can be used for both the diagnosis and treatment of LGI bleeding. A randomized, controlled trial of urgent colonoscopy compared to standard care (scintigraphy and angiography followed by colonoscopy when the other tests were negative) was performed in 100 patients with acute LGI bleeding. Although the bleeding source was definitively diagnosed in 42% in the colonoscopy arm versus only 22% in the standard care group, there was no difference in outcomes, including rebleeding and hospital stay [13]. Although the diagnostic yield for colonoscopy has been reported to range from 74% to 100% [14], colonoscopy can be very challenging in the face of major active bleeding, which can obscure the endoscopist’s view. Whether to use colonoscopy or radiologic testing for initial diagnosis will depend on local expertise and availability. A recent randomized trial [15] of patients with hematochezia and a negative upper endoscopy revealed that patients undergoing urgent lower endoscopy had essentially the same clinical outcome as those who had elective colonoscopy.

A negative arteriogram after a positive nuclear or CT study is not uncommon. In one recent study angiography revealed active extravasation in only 24% of patients with positive tagged RBC scans [16]. This may result just from the lower sensitivity of arteriography compared to scintigraphy or CT. However, LGI bleeding is frequently intermittent, and thus in many cases the bleeding has simply stopped by the time the arteriogram was done. If the patient has had multiple bleeding episodes without a diagnosis being made, provocative angiography can be used to uncover the location of the bleeding. With this technique, anticoagulants, vasodilators, or thrombolytic drugs can be infused to provoke and identify the source of bleeding. The yield of provocative angiography ranges widely from 31% to 89% [17,18], probably due in part to lack of standardized technique. Despite the fact that this technique precipitates active bleeding, identification of the bleeding source allows treatment, and there are no published reports of a patient has suffering uncontrollable hemorrhage with this technique.

Variants 2 and 3: Lower GI tract bleeding. Active bleeding in a hemodynamically unstable patient or a patient who has required more than 5 units of blood. Colonoscopy localized the bleeding site and treatment was attempted. Ongoing or recurrent bleeding. Next procedure/intervention.

Transcatheter arteriography is rarely used as the first diagnostic test except when the patients is massively bleeding and needs urgent therapy. Arteriography is more likely to identify the source of LGI bleeding in patients who have massive bleeding resulting in either hemodynamic instability or a requirement for transfusion of >5 units of blood [19]. Demonstration of the site of bleeding at arteriography enables the possibility of catheter-directed treatment.

In some cases, endoscopic treatment may fail despite demonstration of the site and etiology of bleeding. Depending on the etiology, operator preference, and clinical presentation, angiographic and surgical options are considered.

Variant 4: Lower GI tract bleeding. Intermittent or obscure nonlocalized recurrent bleeding. Next procedure/intervention (assumes prior negative endoscopy).

GI bleeding that persists or recurs despite negative upper and lower endoscopic evaluation is commonly referred to as obscure GI bleeding. Often, obscure bleeding originates from the small bowel, but no clear consensus exists on the optimal study to interrogate the small bowel. A meta-analysis of 17 studies compared capsule endoscopy (CE) to push enteroscopy and small-bowel barium radiography. The diagnostic yield was 63%–67% for CE, 28% for push enteroscopy, and 8% for small-bowel barium studies [20]. In a more recent study, patients with obscure bleeding were randomized to CE or small-bowel barium radiography [21]. The diagnostic yield with CE was higher (30% versus 7%); however, the rate of subsequent bleeding was essentially equivalent, thus the improvement in diagnosis did not translate into any outcome improvement. CT, in particular CT enterography, has been used recently in the setting of obscure bleeding. Although there is often concordance, CT occasionally detects lesions not seen on CE and vice versa [22,23]. Huprich et al [23] found that CT enterography had much better sensitivity for detecting small-bowel bleeding sources compared to CE (88% versus 38%) primarily due to detection of small-bowel masses. However, a systematic review of 18 studies revealed CT enterography to have lower sensitivity (34% and 53%, respectively) than CE [24]. Another study also showed that CE made a diagnosis in 57% of patients who had negative CT enterography [25]. Recently, several studies have also compared CE to
MR or MR enterography and shown better diagnostic yields for CE [26,27]. There is not enough evidence to make a clear recommendation between these modalities, and choice will depend in part on local expertise.

**Angiographic Treatment**

Microcatheter technology has allowed super-selective embolization (SSE) to become the most commonly used angiographic intervention, virtually replacing vasopressin infusion as the treatment of choice. The primary situation in which vasopressin infusion is still indicated is when a diffuse source of bleeding is identified and embolization would necessitate occlusion of too much vascular territory.

Technical success rates of SSE for LGI bleeding range from 73% to 100% [28-40]. In this context technical success indicates successful deposition of emboli and elimination of contrast extravasation. When technical failure does occur, it is usually the result of vessel tortuosity or spasm.

Clinical success rates for SSE are usually lower than the technical success rates due to continued bleeding or early rebleeding despite angiographic evidence of a successful embolization. Clinical success in recent series has ranged from 63% to 96%) [28-36] with rebleeding rates ranging from 11.1% to 50% [16,37-40]. However, in some series TAI has provided definitive treatment for 81%-86% of patients [30,33]. The efficacy of TAI varies depending on the location of the bleeding, small-bowel versus colon. Rebleeding is more common after small-bowel embolization than when treating colonic lesions, likely because of the more robust vascular supply and greater number of potential collateral pathways in the small bowel [41]. The pathology causing the bleeding also affects success. A meta-analysis of 25 studies revealed that recurrent bleeding occurred in only 15% of cases of SSE for colonic diverticular bleeding but occurred in 45% of cases when the pathologic lesion (such as angiodysplasia or inflammatory bowel) had a more diffuse arterial blood supply [31]. Coagulopathy is also a well-known risk factor for recurrent bleeding. In the face of coagulopathy, use of an agent that provides mechanical occlusion without requiring stable clot formation may be beneficial. N-butyl cyanoacrylate glue is such an agent and has been shown to provide effective hemostasis even in coagulopathic patients [42], although it does require a fair amount of expertise to use safely.

Signs of minor ischemic injury to the bowel (such as self-limited abdominal pain or asymptomatic serum lactic acid elevation) are not uncommon sequela of LGI embolization. However, major ischemic complications (those requiring treatment) are uncommon. Major ischemic complications have been reported to be as high as 11%, but on average most series report a rate of 3% or less [28-40].

No large prospective, randomized trials have been conducted to compare TAI with surgery for LGI bleeding. However, TAI can be performed at the time of diagnostic arteriography and can be used in patients who may be too ill to tolerate surgery. Even though 7% to 25% of LGI bleeding patients will ultimately require surgery to stop bleeding or deal with the underlying pathology [43,44], stopping hemorrhage through the use of TAI can allow time to stabilize the patient and prep the bowel, both of which will contribute to a better surgical outcome. Consequently, use of TAI in patients with acute LGI bleeding, where active contrast extravasation is seen during diagnostic arteriography, is a safe and relatively effective treatment that should be considered, depending on local experience and expertise.

**Summary of Recommendations**

- In the patient in whom lower GI bleeding has stopped, colonoscopy is usually the preferred initial examination.
- For diagnosing the cause of colonic bleeding, urgent colonoscopy is an effective technique but can be challenging in the face of ongoing bleeding.
- Nuclear scintigraphy is still the most sensitive radiologic test for determining if the patient is actively bleeding. However, CT scanning is almost as sensitive, provides better localization, and may define the pathologic cause of the bleeding.
- Arteriography is most likely to demonstrate the site of bleeding (and guide therapeutic embolization) in patients with evidence of ongoing bleeding (hemodynamically unstable patients, or those who have required transfusion of >5 units of blood).
- For obscure bleeding, there is not a clear consensus whether CE or CT is more effective and they may be complementary.
The effectiveness of TAI varies depending on the pathology causing the bleeding. Diverticular bleeding with a focal arterial supply is more effectively treated than conditions with more diffuse blood supply such as angiodyplasias, tumors, and inflammatory conditions.

TAI is more effective for colonic lesions than for lesions involving the small bowel.

Recurrence of bleeding following technically successful TAI may occur in 14%–65% of patients.

Symptomatic bowel ischemia following TAI is uncommon.

Many of the diagnostic, surgical, and interventional procedures described here are highly specialized. Their availability and utility vary by institutional and operator experience.

Summary of Evidence

Of the 44 references cited in the ACR Appropriateness Criteria® Radiologic Management of Lower Gastrointestinal Tract Bleeding document, 18 are categorized as therapeutic references including 1 well-designed study, 7 good quality studies, and 2 quality studies that may have design limitations. Additionally, 26 references are categorized as diagnostic references including 5 good quality studies and 7 quality studies that may have design limitations. There are 22 references that may not be useful as primary evidence.

While there are references that report on studies with design limitations, 13 well-designed or good quality studies provide good evidence.

Supporting Documents

References

The ACR Committee on Appropriateness Criteria and its expert panels have developed criteria for determining appropriate imaging examinations for diagnosis and treatment of specified medical condition(s). These criteria are intended to guide radiologists, radiation oncologists and referring physicians in making decisions regarding radiologic imaging and treatment. Generally, the complexity and severity of a patient’s clinical condition should dictate the selection of appropriate imaging procedures or treatments. Only those examinations generally used for evaluation of the patient’s condition are ranked. Other imaging studies necessary to evaluate other co-existent diseases or other medical consequences of this condition are not considered in this document. The availability of equipment or personnel may influence the selection of appropriate imaging procedures or treatments. Imaging techniques classified as investigational by the FDA have not been considered in developing these criteria; however, study of new equipment and applications should be encouraged. The ultimate decision regarding the appropriateness of any specific radiologic examination or treatment must be made by the referring physician and radiologist in light of all the circumstances presented in an individual examination.
